Hydrogen peroxide
Photo-driven ORR

ABSTRACT

It is an ideal route to generate hydrogen peroxide (H_2O_2) via selective 2e^- ORR powered directly by sunlight. In this work, we synthesized a metal-free N-doped γ -graphyne catalyst and wired it with n-type semiconductor photoanodes. The introduction of sunlight could lower the onset bias of oxygen reduction reaction (ORR) up to 0.32 V and H_2O_2 was steadily produced without any sacrificial agents and bias. The 2e^- ORR selectivity of N-doped γ -graphyne catalyst was bias dependent, and it reached about 74% at 0 bias in $0.1 \text{ mol}\cdot\text{L}^{-1}$ KOH. Theoretical calculations showed that in-situ pyridinic-N in N-doped γ -graphyne acted as the active site for ORR, accelerating the rate-determining step of proton abstraction. The H_2O_2 yield reached as high as $7.47 \text{ mmol}\cdot\text{h}^{-1}\text{g}^{-1}$, outperformed the reported traditional photocatalytic syntheses of H_2O_2 .

1. Introduction

Hydrogen peroxide (H_2O_2) is a green and convenient oxidant [1,2] as well as a potential energy source for fuel cells [3,4]. It has been widely utilized for bleaching, sterilization, organic synthesis, and environmental remediation [5,6]. Compared with the commercial anthraquinone method [7,8], experimental synthesis from H_2 and O_2 over noble metal catalysts (Au, Pd, and Pt) [9,10], and 2e^- electrocatalytic ORR [11–13], semiconductor photocatalysis, involving only H_2O and O_2 , is a burgeoning and ideal way for H_2O_2 production [14]. However, traditional photocatalytic systems suffer from serious back reaction and hole trapping agents are usually necessary.

The combination of electrocatalysis and photoelectrochemical (PEC) is an inspiring route that shares the advantages of solar-driving and suppresses back reaction. In this context, Fan and Cui et al. designed a PEC cell in tandem with a single perovskite solar cell device and achieved a solar-to-hydrogen conversion efficiency of up to 6.2% [15]. Glowacki et al. designed PEC cells that separated two half-reactions to address the loss of H_2O_2 and an H_2O_2 concentration of $3 \text{ mmol}\cdot\text{L}^{-1}$ was achieved [16]. Chen et al. combined Zn-air battery with a

polythiophene photocathode and boosted the output voltage from 1.38 V to 1.78 V [17]. Reisner et al. constructed a photosystem II by wiring dye-sensitized photoanode to hydrogenase for water splitting [18]. Xuan et al. [19] and Ryu et al. [20] employed both photoanode and photocathode for PEC water splitting. Li et al. introduced light and polythiophene electrode into H_2 - O_2 fuel cells and the onset potential shifted from 0.66 to 1.34 V [21]. They further constructed a $\text{NiFeO}_x/\text{BiVO}_4$ -polythiophene dual-photoelectrode system to achieve a high H_2O_2 concentration of $110 \text{ mmol}\cdot\text{L}^{-1}$ [22].

Herein, a dual-electrode bias-free solar-driven device was run in $0.1 \text{ mol}\cdot\text{L}^{-1}$ KOH solution without any sacrificial agents. As displayed in Scheme 1a, n-type semiconductor and oxygen reduction reaction (ORR) electrocatalyst were employed as the photoanode and cathode, respectively. Under the irradiation of light, photo-induced holes and electrons were generated on n-type semiconductor photoanodes. Oxygen evolution reaction (OER) was driven by the photo-induced holes from n-type semiconductor photoanode while the photo-induced electrons would transport to the cathode to reduce oxygen into H_2O_2 . Compared with electrocatalytic ORR (Scheme 1b), the introduced light could lower the onset bias of ORR so that external power source was no longer essential.

¹ QiaodanLi and Yang Chen contributed equally to this work.

In comparison with traditional photocatalytic H_2O_2 generation (Scheme 1c), the dual-working-electrode system would promote the separation of photo-induced carriers and avoid the reversible reaction of H_2O_2 decomposition.

γ -graphyne is a new two-dimensional (2D) carbon allotrope that consists of sp -hybridized and sp^2 -hybridized carbon [23,24]. We have synthesized γ -graphyne for the first time through a mechanochemistry method [25], and applied it in the field of photocatalysis [26,27], electrocatalytic oxygen evolution [28], and lithium-ion batteries [29,30]. In this work, N-doped γ -graphyne was mechanosynthesized and the ORR 2e^- selectivity was demonstrated by rotating disk electrode (RDE) technique. The ORR 2e^- selectivity of N-doped γ -graphyne depended strongly on the applied potential. Employing the photo-induced electrons of TiO_2 electrode as driving force, the onset bias of ORR was lowered up to 0.32 V to efficiently generate H_2O_2 under no bias with a H_2O_2 selectivity of about 74%.

2. Experimental details

2.1. Synthesis of N-doped γ -graphyne

A mechanochemical route was implemented to fabricate N-doped γ -graphyne. Typically, 2 mL benzene, 0.15 mL pyridine, 10.0 g CaC_2 , 35 mL absolute ethanol were mixed in a stainless-steel pot (250 mL) with 375 g stainless steel balls. The pot was sealed and rotated by a planetary ball mill (TENCAN QXQM-2, China) at 600 rpm for 8 h, then at 450 rpm for another 8 h. To avoid overheating, a cooling interval of 15 min was implemented every 30 min during the milling. After ball milling, the obtained slurry was annealed in N_2 at 260 $^\circ\text{C}$ for 3 h. The annealed solid was etched by dilute nitric acid ($0.1 \text{ mol}\cdot\text{L}^{-1}$) several times under ultrasonic treatment until no Fe^{3+} could be detected in the etching solution. Finally, the purified N-doped γ -graphyne was separated by centrifugation and drying. The calculated molar ratio of N was about 0.6% in the as-prepared N-doped γ -graphyne according to the stoichiometric proportion.

The general chemicals, pretreatments, and characterization details for the samples are provided in [Supporting Information](#).

2.2. Fabrication of N-doped γ -graphyne electrodes

1.6 mg as-prepared N-doped γ -graphyne was weighted and dispersed in 50 mL H_2O and 100 mL 5 wt% Nafion solution by ultrasonic agitation. Then 5 μL N-doped γ -graphyne glue was dropped onto rotating disk electrodes (5 mm in diameter) supplied by Pine Instrument Company, and 2 μL N-doped γ -graphyne glue was dropped onto CHI-104 glassy carbon electrode (3 mm in diameter) supplied by CHI Company. Both

support electrodes were previously polished by alumina slurries (0.05 μm), ultrasound washed in 50% ethanol solution, dried under nitrogen gas, and finally calibrated with $\text{Fe}(\text{CN})_6^{3-}/\text{Fe}(\text{CN})_6^{4-}$ redox couples.

2.3. Electrochemical measurements

A PLS-SXE300BF Xe lamp from PerfectLight Company was selected as the light source for photoelectrochemical measurements. The pristine ORR performance of N-doped γ -graphyne was implemented by a three-electrode system on a CHI-760 electrochemical workstation, using N-doped γ -graphyne@RDE as the working electrode, graphite rod (99.99999%) as the counter electrode, and Hg/HgO electrode as the reference electrode. The ORR performance of N-doped γ -graphyne under the driven of photoinduced electrons was characterized by a dual-electrode system on a CHI-760 electrochemical workstation, using N-doped γ -graphyne@RDE as working electrode and TiO_2 with different areas as counter and reference electrodes. The H_2O_2 generation performance of the device was implemented in a CH2010 H-type electrolytic cell with an F-type aeration tube purchased from Tianjin Aida Hengsheng Science-Technology Development Co., Ltd. An N117 Nafion membrane (proton exchange membrane) from Dupont Company was employed to separate the H-type electrolytic cell. N-doped γ -graphyne@glassy carbon was used as working electrode and a $2 \text{ cm} \times 2 \text{ cm}$ TiO_2 was chosen as counter and reference electrode. The linear sweep voltammograms (LSV), cyclic voltammograms (CV), and amperometric current-time curves of the dual-electrode device were tested on a CHI-660 electrochemical workstation at 0 bias.

3. Results and discussion

3.1. Characterization of N-doped γ -graphyne

The elementary composition and chemical structure of N-doped γ -graphyne were systemically characterized by EDX, Raman spectroscopy, and XPS. Fig. 1a displays a typical EDX spectrum for the N-doped γ -graphyne sample, in which the molar ratio of carbon was 98.38%. Raman spectrum was also employed to characterize the bond structure in the as-prepared sample (Fig. 1b). The bands at around 1836 cm^{-1} and 1971 cm^{-1} are attributed to the stretching vibration of sp -hybridized carbon [31]. The D band at around 1335 cm^{-1} comes from the defects and disorder structures of the carbonaceous solid, while the G band at around 1582 cm^{-1} corresponds to stretching of in-phase stretching vibration of sp^2 -hybridized carbon [32]. The intensity ratio of the D and G band (I_D/I_G) was 1.22 for N-doped γ -graphyne, which was higher than that of undoped γ -graphyne (0.66) [28], indicating more defects were

introduced by N-doping. These results are accordant with the theoretical calculations [33] and experimental results from N-doped γ -graphdiyne [34–37].

The C1s core-level XPS spectrum of N-doped γ -graphyne was deconvoluted into five peaks at 284.0, 284.9, 285.4, 286.8, and 288.4 eV (Fig. 1c), indexing to the C1s orbital of C = C (sp^2), C \equiv C (sp), C = N (sp^2), C–O (sp) and C = O (sp^2), respectively [35–37]. The integral area ratio of sp -hybridized to sp^2 -hybridized carbon was around 1, which is consistent to the theoretical composition for γ -graphyne. The origin of oxygen should be associated with the surface-absorbed air [38], which has been reported in other graphyne materials [32–34]. The pyridinic-N (398.6 eV), pyrrolic-N (399.7 eV), and graphitic-N (400.7 eV) were assigned in the N1s core-level spectrum (Fig. 1d), revealing the presence of doped N [34,39]. The pyridinic-N originates from pyridine is widely considered as ORR active sites for carbon catalysts [40], while the graphitic-N and pyrrolic-N are usually reorganized during the annealing process due to their high thermal stability [41]. The molar content of pyridinic-N is 47.5%, which would be capable to greatly improve the ORR activities of the prepared N-doped γ -graphyne.

Fig. 2a shows a TEM image of the as-prepared N-doped γ -graphyne, in which a 2D overlapped nanosheets morphology with the size of 0.6–1 μ m can be observed. The size and thickness of nanosheets were further visualized by tapping-mode AFM imaging. The powders were dispersed in ethanol, diluted by a factor of 10^{10} , and deposited onto the monocrystalline silicon pieces. As shown in Fig. 2b, the N-doped γ -graphyne exhibited a 2D structure with a size of around 0.3–0.6 μ m. A typical line profile was inserted to show the thickness of about 1.8–2.1 nm, corresponding to 5 or 6 layers of the N-doped γ -graphyne.

Theoretical calculations illustrated that γ -graphyne belongs to the hexagonal crystal system with hexagonal 2D crystal lattices of $a = b = 0.69$ nm [42,43]. SAED patterns were also measured for the as-prepared N-doped γ -graphyne, typical hexagonal diffraction spots coupled with diffraction rings were observed, indicating that the monocrystalline characteristic of γ -graphyne is destroyed to some degree with more defects after N doping. The diffraction spots/rings were indexed to (330) and (633) lattice planes. HRTEM image also reveals the (330) lattice plane according to the lattice fringes of 0.22 nm (Fig. 2c). An interlayer spacing of about 0.35 nm was observed at the edge of the N-doped γ -graphyne. Therefore, the as-prepared N-doped γ -graphyne consists of a 2D structure similar to γ -graphyne (Fig. 2d), and the N-doping sites are in-situ inherited from the pyridine precursors.

The band structure of the as-prepared N-doped γ -graphyne was determined by UV–vis DRS spectra and Mott-Schottky plots. The curve of transformed Kubelka-Munk function against photon energy was obtained from UV–vis DRS spectra illustrated the optical band gap of about

1.1 eV (Fig. S1a), which is consistent to the theoretical calculation that N-doped γ -graphyne was a semiconductor with an indirect band gap [44]. A negative slope was further observed in the Mott-Schottky plots (Fig. S1b), implying an n-type characteristic for the as-prepared sample. For an n-type semiconductor, the conduction band is usually close to the flat band potential. Thus, the conduction band of N-doped γ -graphyne was estimated to be around -1.04 V vs NHE. Fig. S2 drawn the energy band structure for the as-prepared N-doped γ -graphyne, the high level of the valence band might be in favor of restraining the oxidation of H_2O_2 .

To explore the pristine ORR performance of N-doped γ -graphyne, N-doped γ -graphyne/GC electrode was employed as the working electrode in a three-electrode system. Fig. 3a shows the linear sweep voltammetry (LSV) curves in 0.1 M KOH electrolyte, at different rotation rates varying from 400 to 1600 rpm. The onset potential was 0.75 V vs RHE and one reduction peak could be observed at 0.43 V vs RHE, implying a $2e^-$ reaction might happen if the applied potential is more positive than 0.43 V vs RHE. The electron transfer numbers (η) was calculated by Koutecky-Levich curves [45], as detailed in the Supporting Information. When the applied potential was more positive than 0.43 V vs RHE, the η was calculated to be approximately 2.5 at 0.43, 0.49, and 0.54 V vs RHE (Fig. 3b), which confirmed the $2e^-$ transfer process. The relative error might be ascribed to the H-type electrolytic cell and turbulent flow. When the applied potential was more negative than 0.30 V vs RHE, the calculated η increased with the shift of applied potential from 0.30 to 0.10 V vs RHE (Fig. S3), illustrating the potential-dependent change of electron transfer process from $2e^-$ to $4e^-$. The potential-dependent H_2O_2 selectivity was further confirmed by rotating ring-disk electrode (RRDE) [46] at 1600 rpm. As shown in Fig. S4, positive current could be observed on the Pt ring, illustrating the formation of H_2O_2 . The corrected ring current (collection coefficient: 25%) approached to the disc current at the potential more positive than 0.7 V vs RHE, and did not increase with the increasing of disc current. Thus, N-doped γ -graphyne is expected to avoid the potential-dependent drop of H_2O_2 selectivity by working under a low overpotential.

3.2. H_2O_2 generation by bias-free solar-driven device

The ultimate objective for photosynthetic H_2O_2 generation is that H_2O_2 could be generated efficiently and cost-effectively without any sacrificial agents and bias. We employed TiO_2 electrodes as the photoanode and wired the as-prepared N-doped γ -graphyne as the cathode to construct the bias-free solar-driven device (Fig. 4a) for H_2O_2 generation. TiO_2 is one of the most recognized photoanode materials with multiple advantages, including its low cost, earth abundance, and commercial availability. TiO_2 photoanode is an ideal choice for verifying the

feasibility of the newly-developed PEC device. The synthesis and energy levels of the as-utilized TiO₂ are presented in Figs. S5 to S6.

Fig. 4b exhibits the LSV curves of the device under dark and irradiation. Under dark, ORR started at the bias of -0.24 V and the current density was very low. When the light was turned on, the bias for starting the ORR shifted towards $+0.09$ V. Under the bias of 0 V, a negative current density was exhibited, indicating that ORR could happen with photo-induced electrons from the TiO₂ photoanode even with no bias. The appearance of reduction peaks illustrates that the ORR should be a $2e^-$ process with a bias lower than -0.3 V.

For this dual-electrode device, the current densities were no longer correlated with the rotating rate of RDE as the reaction was no longer a diffusion control. In order to study the rate-determining step, we increased the area of TiO₂ electrode from 1 to 2 cm². The doubled photoanode area increased more photo-induced carriers under irradiation. As shown in Fig. 4c, the current densities under irradiation increased by 52%, indicating that the number of photo-induced carriers was the rate-determining step. Besides, the onset bias barely changed because the energy of the photo-induced electrons is constant for TiO₂ fabricated via the same method. The open-circuit voltage of the device under intermittent illumination also described the role of photo-induced electrons. As illustrated in Fig. 4d, the open-circuit voltage underwent a positive shift for ORR under irradiation, illustrating photo-induced electrons would lower the threshold of ORR. However, the open-circuit voltage did not shift according to the area of TiO₂ photoanode because increasing the area of photoanode would not contribute to the energy of photo-induced electrons, though the number of electrons increased.

In order to confirm the importance of the energy of photo-induced electrons, one Fe₂O₃ photoanode (1 cm²) was used to take the place of

the TiO₂ photoanode for comparison. As shown in Figs. S7 to S9, the current densities were larger than those with the TiO₂ electrode (1 cm²) as photoanode. This is reasonable because the bandgap of Fe₂O₃ is much narrower than that of TiO₂, in which more photons could be absorbed and more photo-induced carriers would be generated. However, the onset bias was -0.10 V, indicating that the device could not produce H₂O₂ from ORR with 0 applied bias. This might be associated with the position of conduction band of Fe₂O₃. The reduction ability of the photo-induced electrons produced by Fe₂O₃ photoanode is not as strong as those produced by TiO₂ photoanode because of its lower conduction level. Since the photo-induced carriers are the driving force of this device, the semiconductor photoanode materials (area and energy level) should be dominant factors in this unbiased device for photosynthetic H₂O₂ generation.

To demonstrate the bias-free H₂O₂ generation performance of the device, an H-type electrolytic cell with a Nafion membrane was employed (Fig. S10). The Nafion membrane isolated the TiO₂ photoanode and N-doped γ -graphyne cathode to prevent the generated H₂O₂ on cathode from being oxidized by anode during the reaction. The area of TiO₂ photoanode was further increased to 4 cm² according to the size of electrolytic cell in order to supply as many photo-induced electrons as possible. The influence of the light intensity was first studied. As shown in Fig. S11, stronger light irradiation induced larger current densities at the cathode electrode because the number of photons generated increased with increasing the light intensity (83, 100, 130, 160, 186 mW·cm⁻²) under 0 bias. The onset bias also shifted towards more positive bias, illustrating stronger light irradiation would provide stronger driving force via more photo-induced carriers per unit area. Amperometric i-t curve of the device was then implemented with 0 V bias under irradiation (AM1.5; 100 mW·cm⁻²) for 4 h (the upper limit of

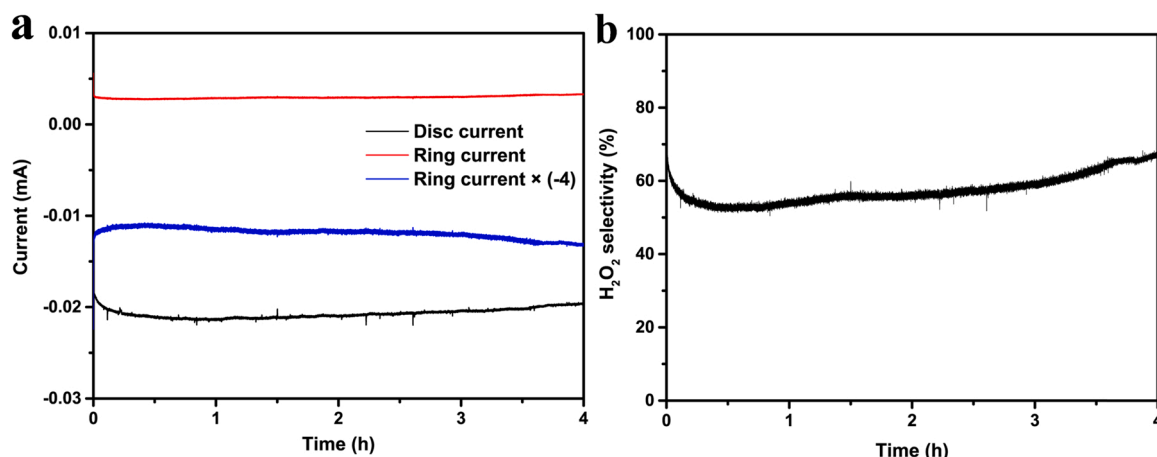

Fig. 5. (a) Amperometric i-t curve of the dual-electrode device implemented by rotating ring-disk electrode in O_2 -saturated electrolytes under irradiation with 0 bias and (b) the H_2O_2 selectivity.

working time of our Xe lamp) in $0.1 \text{ mol}\cdot\text{L}^{-1}$ KOH. The current density kept stable (Fig. 5a) and the H_2O_2 selectivity increased as the reaction progress (Fig. 5b).

3.3. The cyclic H_2O_2 generation activity

The device was operated for three circles to reveal the cyclic H_2O_2 generation activity. The charge-time curves (Fig. 6a) were relatively smooth during the whole reaction, despite the system disturbances of photocurrent. During cyclic reactions, the transfer of photo-induced electrons increased steadily. The H_2O_2 yield was measured by spectroscopic titration with H_2SO_4 solution ($1 \text{ mol}\cdot\text{L}^{-1}$) of KMnO_4 ($10^{-4} \text{ mol}\cdot\text{L}^{-1}$) according to the reaction: $2\text{KMnO}_4 + 5\text{H}_2\text{O}_2 + 3\text{H}_2\text{SO}_4 \rightarrow \text{K}_2\text{SO}_4 + 2\text{MnSO}_4 + 5\text{O}_2 + 8\text{H}_2\text{O}$. Briefly, 2 mL KMnO_4 solution and 1 mL electrolyte were mixed and the absorbance at 526 nm and 545 nm was recorded by a UV-2300 UV-vis spectrophotometer. The yield of H_2O_2 was calculated by the calibration curve of KMnO_4 solution. The measured H_2O_2 yield efficiency reached as high as $7.47 \text{ mmol}\cdot\text{h}^{-1}\text{g}^{-1}$, outperformed previously-reported studies involving hole trapping agent (s) for the synthesis of H_2O_2 via traditional photocatalysis route (Table 1). Comparing to the ideal H_2O_2 yield calculated from the charge-time curve, H_2O_2 selectivity reached up to 74% (Fig. 6b), indicating an efficient $2e^-$ ORR for the N-doped γ -graphyne in this bias-free device.

The electrochemical active surface area (ECSA) of the N-doped γ -graphyne electrode before (Fig. 7a) and after (Fig. 7b) reaction were estimated to illustrate the stability and continuous improved H_2O_2

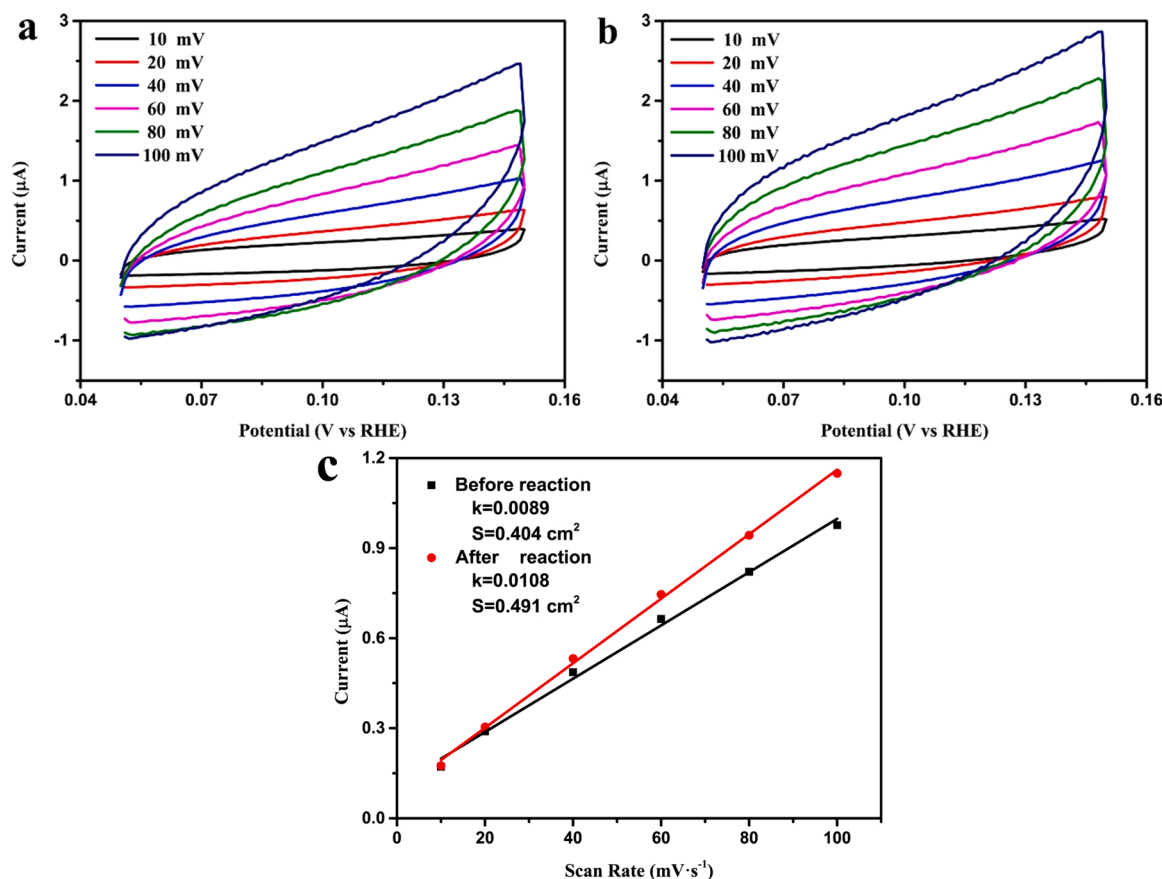

Fig. 7. Cyclic voltammograms of N-doped γ -graphyne@ glassy carbon electrode in 0.1 mol·L⁻¹ KOH solution in a non-Faradaic region (a) before and (b) after cyclic ORR reaction. (c) The relationship between charging currents at 0.1 V vs SCE and scan rate.

selectivity. CV curves (three-electrode systems) were implemented under dark in 0.1 mol·L⁻¹ KOH solution at different scan rates. A small potential window of 0.05–0.15 V vs SCE was selected because N-doped γ -graphyne did not show any faradaic response within this window. The ECSA was calculated from the double-layer capacitance which was determined by the double-layer charging current (i_c) and scan rate (ν): $ECSA = \frac{C_{dl}}{C_s} = \frac{i_c/\nu}{C_s}$, in which C_s was 22 μ F·cm⁻² for carbon materials in alkaline solutions [56,57]. According to Fig. 7c, the ECSA increased 21.5% after cyclic reaction, illustrating the active sites of N-doped γ -graphyne were created (more exposed surface of N-doped γ -graphyne) during the cyclic H₂O₂ generation. A similar phenomenon has also been reported for γ -graphyne materials in our previous work [28]. The increasing ECSA may result from the continuous improvement of H₂O₂ generation on N-doped γ -graphyne with enhanced interfacial interactions between the electrode and electrolyte solution in this device since the lone pairs of electrons in N is beneficial to the absorbance of hydrogen ion.

3.4. Mechanisms

Density functional theory (DFT) calculations were carried out to understand the mechanism of the 2e⁻ ORR process on N-doped γ -graphyne. A molecular fragment of N-doped γ -graphyne (Fig. 8a) containing 116 carbon atoms and 2 nitrogen atoms was built as the model structure for the calculation. The accurate coordinates of these atoms after geometry optimization are presented in the Supporting Information. Then, the possible ORR pathways on N-doped γ -graphyne were proposed by assuming pyridinic-N, sp²-hybridized carbon, and sp-hybridized carbon as active sites, respectively. Subsequently, the models of the possible reaction intermediates were built and their frequencies

were calculated with DMol3 module by the m-GGA M06-L functional. The detailed coordinates of the atoms in intermediates and the calculation results of total energy (Table S1) were supplied in the Supporting Information. Fig. 8b–d shows the relative energy of the possible reaction steps, in which the total energy of N-doped γ -graphyne at ground state was used as zero points. The energy change of the step of “NGY-OO²⁻ + H₂O \rightleftharpoons NGY-OOH⁻” is the highest, illustrating this step was the rate-determining reaction for 2e⁻ ORR. When pyridinic-N was introduced as the active sites (Fig. 8b), the energy change of this step was lowered greatly. The introduction of pyridinic-N would accelerate the slowest step of 2e⁻ ORR and improve the H₂O₂ generation efficiency for γ -graphyne. Furthermore, the total energy change of the proton abstraction would be smaller than the injection of the first electron when pyridinic-N played the role as active sites, which might be the reason for the high H₂O₂ selectivity.

The pH-dependence of N-doped γ -graphyne in this device was also unraveled. LSV curves and electrochemical impedance spectra of the device were investigated in O₂-saturated electrolytes with different pH value. K₂SO₄ was employed as supporting electrolyte to guarantee the ionic strength constant at 0.1 mol·L⁻¹. The current densities of the device showed a strong pH dependence (Fig. 9a). In acid electrolyte (H₂SO₄ solution) and neutral electrolyte (K₂SO₄ solution), the current densities increased gradually with the increase of pH values. In alkaline electrolyte (KOH solution), the onset bias underwent a positive shift while the current densities increased greatly with the increase of pH values. Thus, the device is expected to work in alkaline solution better and 0.1 mol·L⁻¹ KOH is the most suitable electrolyte.

The Nyquist plots at 0 bias was implemented to analyze the charge transfer process at the interface. As displayed in Fig. 9c–d, one small semicircle at high frequencies and another large circular arc at low

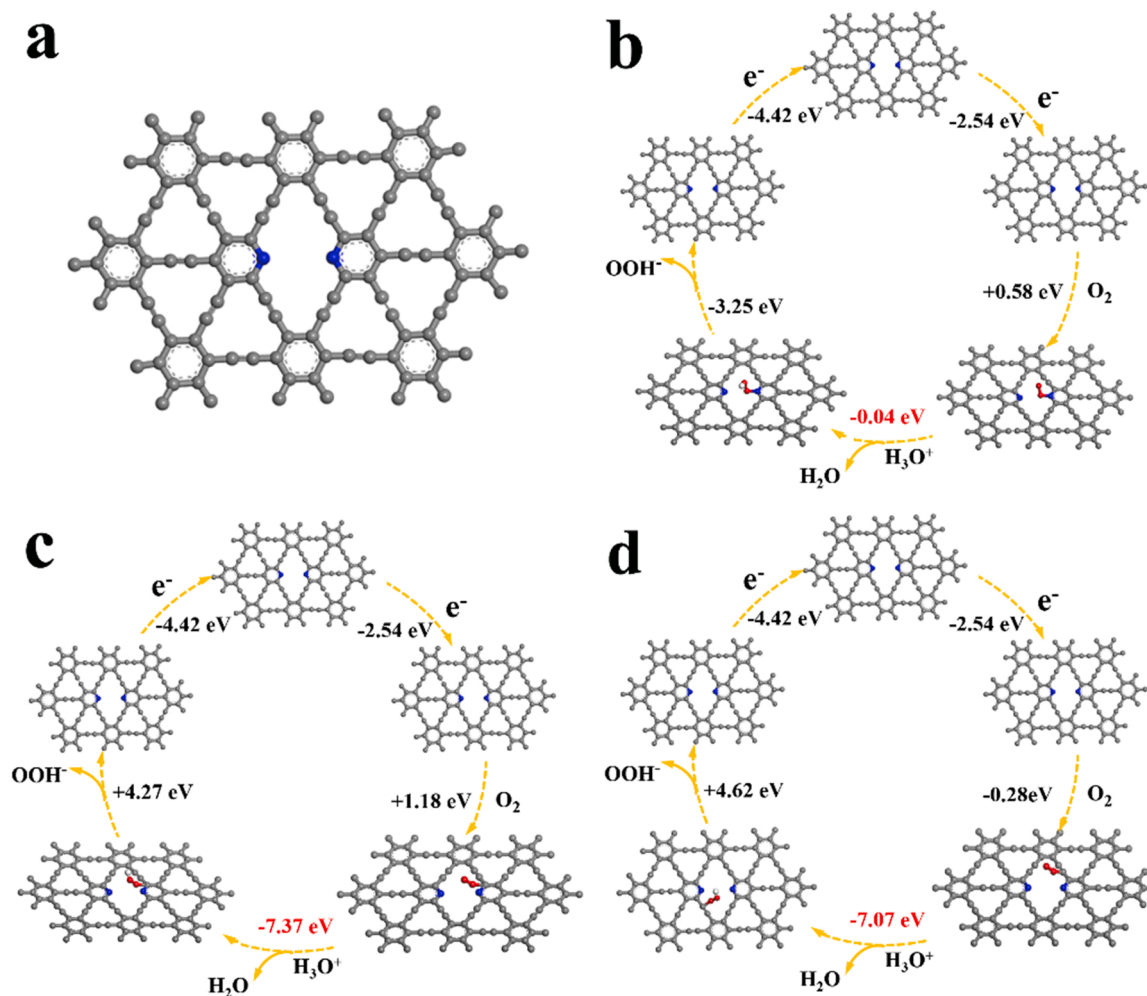

Fig. 8. (a) The model of N-doped γ -graphyne for calculation here and (b,c,d) the total energy profiles of key possible ORR pathways on N-doped γ -graphyne. The active site is (b) pyridinic-N, (c) sp^2 -hybridized carbon, and (d) sp -hybridized carbon, respectively.

frequencies were observed. The Nyquist plots were fitted according to the equivalent circuit model inserted in Fig. 9c and the fitting data were provided in Table S2. The R_i is the internal resistance; R_{ct1} and $CPE1$ is the resistance and constant phase element relevant to the smaller semicircle; R_{ct2} and $CPE2$ is the resistance and constant phase element related to the larger circular arc. The relationships between impedance and pH value were presented in Fig. 9b. The values of R_{ct2} were more than two orders of magnitudes larger than those of R_i and R_{ct1} , illustrating that R_{ct2} described the rate-determining step (the OER at photoanode, the ORR at cathode). R_{ct1} exhibited similar behavior in H_2SO_4 and KOH, which implied the corresponding processes were not sensitive to H^+ or OH^- (the transport of photo-induced electrons). The values of R_{ct2} increased with the increase of pH values, which was consistent with the current densities in various electrolytes. The interfacial OER and ORR processes at electrodes were significantly influenced by electrolyte, contributing greatly to the pH-dependent performance of this solar-driven device.

The impact of the 1.62% stainless steel impurities was also considered. The impurities from the mechanical friction of ball-milling balls and pots are hard to completely avoid due to the characteristic of mechanochemistry. However, the mechano-synthesized sample has been etched by dilute nitric acid ($0.1 \text{ mol}\cdot\text{L}^{-1}$) several times under ultrasonic treatment during the days of etching process to remove stainless steel impurities on the surface. The residual impurities should be wrapped by the N-doped γ -graphyne because the stainless steel impurities that can interact with the acid etching solution must have been

removed. The undoped γ -graphyne synthesized by the same method also contained about 1% stainless steel impurities, but exhibited very poor ORR catalytic activity (Fig. S12), illustrating the contribution of stainless steel impurities, if any, could be neglected.

4. Conclusions

In summary, we have successfully synthesized in-situ N-doped γ -graphyne through a mechanochemical route and applied it for photosynthetic H_2O_2 generation. This newly-developed metal-free carbon material enabled the synthesis of H_2O_2 through $2e^-$ ORR in alkaline solution. The N-doped γ -graphyne electrode was wired with a TiO_2 photoanode and the onset bias of ORR was lowered up to 0.32 V. H_2O_2 was steadily produced under 0 bias with the irradiation of light. The H_2O_2 selectivity reached up to 74% and the H_2O_2 yield rate was as high as $7.47 \text{ mmol}\cdot\text{h}^{-1}\cdot\text{g}^{-1}$ without any bias and sacrificial agent, outperformed previously reported syntheses of H_2O_2 via traditional photocatalytic routes with hole trapping agents. Theoretical calculations suggested that pyridinic-N in the N-doped γ -graphyne network is the active site, which lowered the rate-determining step of proton abstraction. In comparison with traditional photocatalytic H_2O_2 generation, the dual-working-electrode system developed in this study could promote the separation of photo-induced carriers and avoid the reversible reaction of H_2O_2 decomposition. The newly-developed methodology is rather general, which can be applied for photocatalytic reactions beyond the H_2O_2 generation.
